

Perceptron Explained using Python Example

August 2, 2022 by [Ajitesh Kumar](#) · [2 Comments](#)

In this post, you will learn about the concepts of **Perceptron** with the help of [Python](#) example. It is very important for [data scientists](#) to understand the concepts related to Perceptron as a good understanding lays the foundation of learning advanced concepts of neural networks including deep neural networks ([deep learning](#)).

Conclusions

What is Perceptron?

Perceptron is a machine learning algorithm which mimics how a neuron in the brain works. It is also called as **single layer neural network** consisting of a **single neuron**. The output of this neural network is decided based on the outcome of **just one activation function** associated with the single neuron. In perceptron, the **forward propagation** of information happens. Deep neural network consists of one or more perceptrons laid out in two or more layers. Input to different perceptrons in a particular layer will be fed from previous layer by combining them with different weights.

Let's first understand how a neuron works. The diagram below represents a neuron in the brain. The input signals (x_1, x_2, \dots) of different strength (observed weights, $w_1, w_2 \dots$) is fed into the neuron cell as **weighted sum** via dendrites. The weighted sum is termed as the **net input**. The net input is processed by the neuron and output signal (observer signal in AXON) is appropriately fired. In case the combined signal strength is not appropriate based on decision function within neuron cell (observe activation function), the neuron does not fire any output signal.

Fig 1. Neuron in Human Brain

The following is an another view of understanding an artificial neuron, a perceptron, in relation to a biological neuron from the viewpoint of how input and output signals flows:

The [perceptron](#) when represented as line diagram would look like the following with mathematical notations:

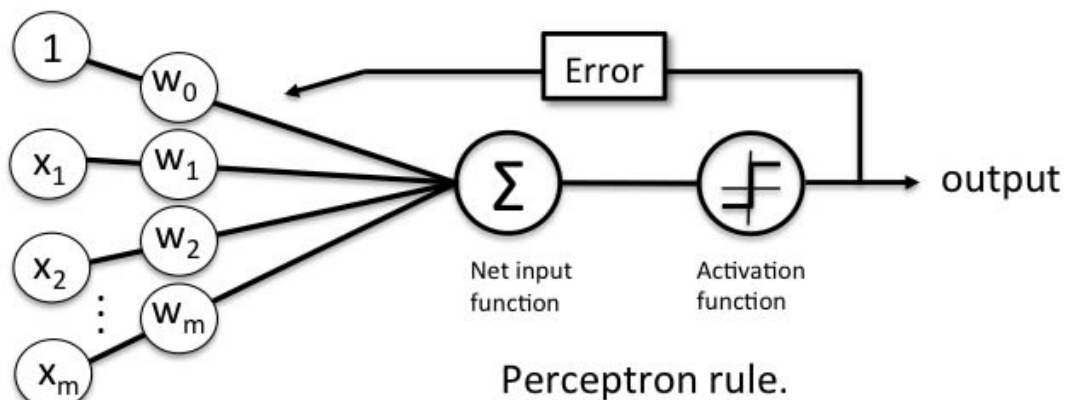

Fig 2. Perceptron – Single-layer Neural Network

Pay attention to some of the following in relation to what's shown in the above diagram representing a neuron:

- **Step 1 – Input signals weighted and combined as net input:** Weighted sums of input signal reaches to the neuron cell through dendrites. The weighted inputs does represent the fact that different input signal may have different strength, and thus, weighted sum. This weighted sum can as well be termed as **net input** to the neuron cell.
- **Step 2 – Net input fed into activation function:** Weighted The weighted sum of inputs or **net input** is fed as input to what is called as **activation function**. The activation function is a non-linear activation function. The activation functions are of different types such as the following:
 - Unit step function
 - Sigmoid function (Popular one as it outputs number between 0 and 1 and thus can be used to represent probability)
 - Rectilinear (ReLU) function
 - Hyperbolic tangent

The diagram below depicts different types of non-linear activation functions.

- **Step 3A – Activation function outputs binary signal appropriately:** The activation function processes the net input based on the **unit step (Heaviside) function** and outputs the binary signal appropriately as either 1 or 0. The activation function for perceptron can be said to be a unit step function. Recall that the **unit step function**, $u(t)$, outputs the value of 1 when $t \geq 0$ and 0 otherwise. In the case of a shifted unit step function, the function $u(t-a)$ outputs the value of 1 when $t \geq a$ and 0 otherwise.
- **Step 3B – Learning input signal weights based on prediction vs actuals:** A parallel step is a neuron sending the feedback to strengthen the input signal strength (weights) appropriately such that it could create an output signal appropriately that matches the actual value. The feedback is based on the outcome of the activation function which is a unit step function. Weights are updated based on the **gradient descent learning algorithm**. Here is my post on gradient descent – [Gradient descent explained simply with examples](#). Here is the equation based on which the weights get updated:

$$w_i \leftarrow w_i + \Delta w_i$$

where

$$\Delta w_i = \eta(t - o)x_i$$

learning rate target value perceptron output input value

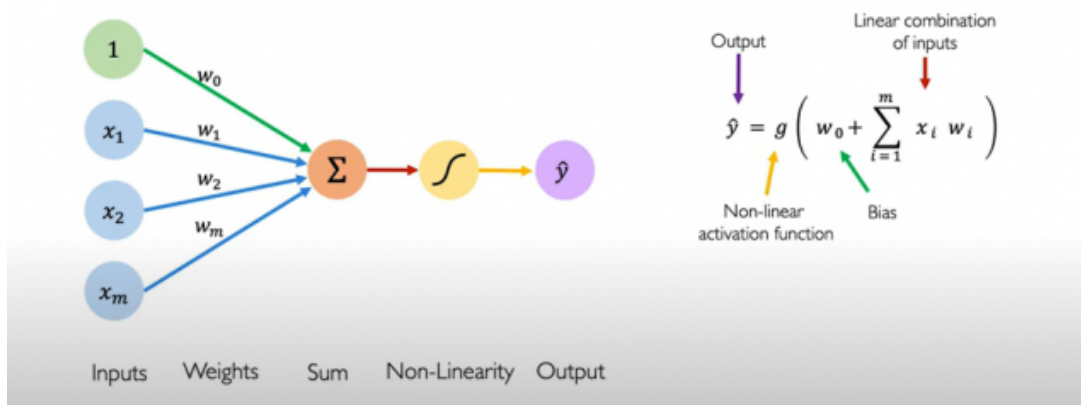

Fig 3. Weight update rule of Perceptron learning algorithm

Pay attention to some of the following in above equation vis-a-vis Perceptron learning algorithm:

- Weights get updated by Δw
- Δw is derived by taking the first-order derivative of the loss function (gradient) and multiplying the output with negative (gradient descent) of learning rate. The output is what is shown in the above equation – the product of learning rate, the difference between actual and predicted value (perceptron output), and input value.

- In this post, the weights are updated based on each training example such that the perceptron can learn to predict closer to the actual output for the next input signal. This is also called **stochastic gradient descent (SGD)**. Here is my post on [stochastic gradient descent](#). That said, one could also try **batch gradient descent** to learn the weights of input signals.

Here is another picture of **Perceptron** that represents the concept explained above.

Perceptron – A single-layer neural network comprising of a single neuron

Perceptron Python Code Example

In this section, we will look each of the steps described in previous section and understand the implementation with the Python code:

- Input signals weighted and combined as net input:** Input signals get multiplied with weights and the sum of all weighted input signal is taken. This sum is called as **net input** and would be fed into activation function. Here is the code for **net input**. Note the dot product of coefficients with input X. Coefficient[0] is multiplied with 1 (bias element).

```
1  '''
2  Net Input is sum of weighted input signals
3  '''
4  def net_input(self, X):
5      weighted_sum = np.dot(X, self.coef_[1:]) + self.coef_[0]
6      return weighted_sum
```

- Activation function invoked with net input:** Net input is fed into activation function and output is determined based on the outcome of unit step function. Here is the code:

```
1  '''
2  Activation function is fed the net input and the unit step function is executed to det
3  '''
4  def activation_function(self, X):
5      weighted_sum = self.net_input(X)
6      return np.where(weighted_sum >= 0.0, 1, 0)
```

- Prediction based on the activation function output:** In Perceptron, the prediction output coincides with (or equal to) the output of activation function which uses unit step function. This is where the Perceptron is different from **ADaptive LInear NEuron** also termed as **Adaline**. The Adaline algorithm implementation will be described in future post. In Adaline algorithm, the **activation function is identity function** and **prediction is done based on unit step function** output.

```
1  '''
2  Prediction is made on the basis of output of activation function
3  '''
4  def predict(self, X):
5      return self.activation_function(X)
```

- Learning weights based on the prediction vs actual:** Weights are learned based on comparing the value of actual label and the predicted label (binary) and applying stochastic gradient descent algorithm to learn weights based on each training example. The idea is to improve on making predictions based on the learning from last training example. Here is the **fit** method which demonstrates the learning of input weights:

```

1  '''
2  Stochastic Gradient Descent
3
4  1. Weights are updated based on each training examples.
5  2. Learning of weights can continue for multiple iterations
6  3. Learning rate needs to be defined
7  '''
8  def fit(self, X, y):
9      rgen = np.random.RandomState(self.random_state)
10     self.coef_ = rgen.normal(loc=0.0, scale=0.01, size=1 + X.shape[1])
11     for _ in range(self.n_iterations):
12         for xi, expected_value in zip(X, y):
13             predicted_value = self.predict(xi)
14             self.coef_[1:] = self.coef_[1:] + self.learning_rate * (expected_value -
15             self.coef_[0] = self.coef_[0] + self.learning_rate * (expected_value - pr

```

Here is how the entire Python code for Perceptron implementation would look like. This implementation is used to train the binary classification model that could be used to classify the data in one of the binary classes. Pay attention to all the methods that are explained previously. Also, pay attention to the score method which is used to measure the accuracy of the model.

```

1  import numpy as np
2  #
3  # Perceptron implementation
4  #
5  class CustomPerceptron(object):
6
7      def __init__(self, n_iterations=100, random_state=1, learning_rate=0.01):
8          self.n_iterations = n_iterations
9          self.random_state = random_state
10         self.learning_rate = learning_rate
11
12         '''
13         Stochastic Gradient Descent
14
15         1. Weights are updated based on each training examples.
16         2. Learning of weights can continue for multiple iterations
17         3. Learning rate needs to be defined
18         '''
19     def fit(self, X, y):
20         rgen = np.random.RandomState(self.random_state)
21         self.coef_ = rgen.normal(loc=0.0, scale=0.01, size=1 + X.shape[1])
22         self.errors_ = []
23         for _ in range(self.n_iterations):
24             errors = 0
25             for xi, expected_value in zip(X, y):
26                 predicted_value = self.predict(xi)
27                 self.coef_[1:] = self.coef_[1:] + self.learning_rate * (expected_valu
28                 self.coef_[0] = self.coef_[0] + self.learning_rate * (expected_value
29                 update = self.learning_rate * (expected_value - predicted_value)
30                 errors += int(update != 0.0)
31             self.errors_.append(errors)
32
33         '''
34         Net Input is sum of weighted input signals
35         '''
36     def net_input(self, X):
37         weighted_sum = np.dot(X, self.coef_[1:]) + self.coef_[0]
38         return weighted_sum
39
40         '''
41         Activation function is fed the net input and the unit step function
42         is executed to determine the output.
43         '''
44     def activation_function(self, X):
45         weighted_sum = self.net_input(X)
46         return np.where(weighted_sum >= 0.0, 1, 0)
47
48         '''
49         Prediction is made on the basis of output of activation function
50         '''
51     def predict(self, X):
52         return self.activation_function(X)

```

```

53     '''
54     Model score is calculated based on comparison of
55     expected value and predicted value
56     '''
57     def score(self, X, y):
58         misclassified_data_count = 0
59         for xi, target in zip(X, y):
60             output = self.predict(xi)
61             if(target != output):
62                 misclassified_data_count += 1
63         total_data_count = len(X)
64         self.score_ = (total_data_count - misclassified_data_count)/total_data_count
65         return self.score_

```

Here is the Python code which could be used to train the model using **CustomPerceptron** algorithm shown above. Note that SKlearn breast cancer data is used for training the model in order to classify / predict the breast cancer.

```

1  import numpy as np
2  from sklearn import datasets
3  from sklearn.model_selection import train_test_split
4  #
5  # Load the data set
6  #
7  bc = datasets.load_breast_cancer()
8  X = bc.data
9  y = bc.target
10 #
11 # Create training and test split
12 #
13 X_train, X_test, y_train, y_test = train_test_split(X, y, test_size=0.3, random_state=42)
14 #
15 # Instantiate CustomPerceptron
16 #
17 prcptn = CustomPerceptron(n_iterations=10)
18 #
19 # Fit the model
20 #
21 prcptn.fit(X_train, y_train)
22 #
23 # Score the model
24 #
25 prcptn.score(X_test, y_test), prcptn.score(X_train, y_train)

```

Executing the above code will print the accuracy score with test and training data set. (0.8888888888888888, 0.9120603015075377)

The code below plots the error vs Epochs. Epoch is a machine learning term used to describe the point at which a model has seen all of the training data once. Training data is fed into the model during Epochs. The number of Epochs is a hyperparameter that can be tuned to improve model performance. Generally, more Epochs will result in better performance, but at the expense of longer training time. When working with large datasets, it is common to run for hundreds or even thousands of Epochs. However, it is important to monitor the model closely to ensure that it is not overfitting the training data.

```

1  %matplotlib inline
2  import matplotlib.pyplot as plt
3
4  plt.plot(range(1, len(prcptn.errors_) + 1), prcptn.errors_, marker='o')
5  plt.xlabel('Epochs')
6  plt.ylabel('Number of updates')
7
8  # plt.savefig('images/02_07.png', dpi=300)
9  plt.show()

```

Sklearn.linear_model Perceptron Example

The following Python code represents usage of [Perceptron classifier from Sklearn.linear_model](#) package.

```

1  from sklearn import datasets
2  import numpy as np
3  from sklearn.model_selection import train_test_split
4  from sklearn.linear_model import Perceptron
5  from sklearn.preprocessing import StandardScaler
6  from sklearn.metrics import accuracy_score
7
8  iris = datasets.load_iris()
9  X = iris.data[:, [2, 3]]
10 y = iris.target
11
12 X_train, X_test, y_train, y_test = train_test_split(
13     X, y, test_size=0.3, random_state=1, stratify=y)
14
15 sc = StandardScaler()
16 sc.fit(X_train)
17 X_train_std = sc.transform(X_train)
18 X_test_std = sc.transform(X_test)
19
20 ppn = Perceptron(eta0=0.1, random_state=1)
21 ppn.fit(X_train_std, y_train)
22
23 y_pred = ppn.predict(X_test_std)
24
25 print('Accuracy: %.3f' % accuracy_score(y_test, y_pred))
26 print('Accuracy: %.3f' % ppn.score(X_test_std, y_test))

```

Conclusions

Here is the summary of what you learned about the Perceptron algorithm with help of Python implementation:

- Perceptron mimics the neuron in the human brain
- Perceptron is termed as machine learning algorithm as weights of input signals are learned using the algorithm
- Perceptron algorithm learns the weight using gradient descent algorithm. Both stochastic gradient descent and batch gradient descent could be used for learning the weights of the input signals
- The activation function of Perceptron is based on the unit step function which outputs 1 if the net input value is greater than or equal to 0, else 0.
- The prediction is also based on the unit step function.
